Abstract

Streaming libraries have become ubiquitous in object-oriented languages, with recent offerings in Java, C#, and Scala. All such libraries, however, suffer in terms of extensibility: there is no way to change the semantics of a streaming pipeline (e.g., to fuse filter operators, to perform computations lazily, to log operations) without changes to the library code. Furthermore, in some languages it is not even possible to add new operators (e.g., a zip operator, in addition to the standard map, filter, etc.) without changing the library.

We address such extensibility shortcomings with a new design for streaming libraries. The architecture underlying this design borrows heavily from Oliveira and Cook’s object algebra solution to the expression problem, extended with a design that exposes the push/pull character of the iteration, and an encoding of higher-kinded polymorphism. We apply our design to Java and show that the addition of full extensibility is accompanied by high performance, matching or exceeding that of the original, highly-optimized Java streams library.

1 Introduction

Recent years have seen the introduction of declarative streaming libraries in modern object-oriented languages, such as Java, C#, or Scala. Streaming APIs allow the high-level manipulation of value streams (with each language employing slightly different terminology) with functional-inspired operators, such as filter, or map. Such operators take user-defined functions as input, specified via local functions (lambdas). The Java example fragment below shows a “sum of even squares” computation, where the even numbers in a sequence are squared and summed. The input to map is a lambda, taking an argument and returning its square. Similarly, the input to filter is a lambda, determining whether its argument is even.
Our work is based on the key observation that streaming operators introduce a separate (domain-specific) sub-language that is interpreted during program run-time. This observation is inspired by the architecture of the Java 8 streams library, which aggressively manipulates the streaming pipeline, as if the library calls were syntax nodes of an interpreted program. A pipeline of the form “\texttt{of(...).filter(...).map(...).sum()}” is formed with \texttt{sum} being at the outermost layer, i.e., right-to-left as far as surrounding code is concerned. However, when the terminal operator (\texttt{sum}) is reached, it starts evaluation over the stream data by eventually invoking an iteration method in operator \texttt{of}. It is this method that drives iteration and calls the operators left-to-right. The result of such manipulation is significant performance gains. The Java 8 streams implementation effectively changes external (pull-style) iteration into internal (push-style). Recent benchmarking studies [2] report that, with this change, the library avoids a number of indirect calls and allows much better downstream optimizations.

The problem with existing library designs is that there is no way to alter the semantics of a streaming pipeline without changing the library itself. This is detrimental to library extensibility. For instance, a user may want to extend the library in any of the ways below:

- Create push-vs-pull versions of all operators.
- Create a logging interpretation of a pipeline, which logs actions and some intermediate results.
- Create an interpretation computing asynchronous versions of an evaluation (futures-of-values instead of values).
- Create an optimizing interpretation that fuses together operators, such as neighboring filters or maps.

Additionally, the current architecture of streaming libraries prevents the introduction of new operators, precisely because of the inflexible way that evaluation is performed. As discussed above, Java streams introduce push-style iteration by default. This approach would yield semantic differences from pull-style iteration if more operators, such as \texttt{zip}, were added to the library. Furthermore, in some languages the addition of new operators requires editing the library code or using advanced facilities: in Java such addition is only possible by changing the library itself, while in C# one needs to use extension methods, and in Scala one needs to use implicits.

In our work, we propose a new design and architecture for streaming libraries for Java-like languages, to maximize extensibility without sacrificing on any other axis. Our approach requires no language changes, and only leverages features found across all languages examined – i.e., standard parametric polymorphism (generics). Underlying our architecture is the object algebra construction of Oliveira and Cook [13] and Oliveira et al. [14]. This is combined with a library design that dissociates the push or pull nature of iteration from the operators themselves, analogously to the recent “defunctionalization of push arrays” approach in the context of Haskell [22].

Based on this architecture, we have implemented an alternative stream library for Java\textsuperscript{1}. In our library, the pipeline shown earlier gets inverted and parameterized by an \texttt{alg} object, which designates the intended semantics. For instance, a plain Java-streams-like evaluation would be written:

\begin{verbatim}
int sum = IntStream.of(v)
    .filter(x -> x % 2 == 0)
    .map(x -> x * x)
    .sum();
\end{verbatim}

\textsuperscript{1} \url{http://biboudis.github.io/streamalg}
A. Biboudis, N. Palladinos, G. Fourtounis, and Y. Smaragdakis

```java
PushFactory alg = new PushFactory();
int sum = Id.prj(
    alg.sum(
        alg.map(x -> x * x, 
        alg.filter(x -> x % 2 == 0, 
        alg.source(v))))).value;
```

(The `Id.prj` and `value` elements, above, are part of a standard pattern for simulating higher-kinded polymorphism with plain generics. They can be ignored for the purposes of understanding our architecture. We discuss the pattern in detail in Section 4.)

Although the above fragment is slightly longer than the original, its elements are highly stylized. The user can adapt the code to other pipelines with trivial effort, comparable to that of the original code fragment in Java 8 streams. Most importantly, if the user desired a different interpretation of the pipeline, the only necessary change is to the first line of the example. An interpretation that has pull semantics and fuses operators together only requires a new definition of `alg`:

```java
FusedPullFactory alg = new FusedPullFactory();
... // same as earlier
```

Such new semantics can be defined externally to the library itself. Adding `FusedPullFactory` requires no changes to the original library code, allowing for semantics that the library designer had not foreseen.

This highly extensible design comes at no cost to performance. The new architecture introduces no extra indirection and does not prevent the JIT compiler from performing any optimization. This is remarkable, since current Java 8 streams are designed with performance in mind (cf. the earlier push-style semantics). As we show, our library matches or exceeds the performance of Java 8 streams.

Overall, our work makes the following contributions:

- We introduce a new design and architecture\(^2\) for streaming libraries and argue for its benefits, in terms of extensibility and low adoption barrier (i.e., use of only standard language features), all without sacrificing performance.
- We demonstrate extensibility and provide several alternative semantics for streaming pipelines, all in an actual, publicly available implementation.
- We provide an example of the use of object algebras in a real-world, performance-critical setting.

## 2 Background

We next discuss streaming libraries in Java, Scala, C#, and F#. We also introduce *push/internal vs. pull/external* iteration, via reference to specific facilities in these libraries.

### 2.1 Java

Java is a relative newcomer among streaming facilities, yet features a library that has received a lot of engineering attention. We already saw examples of the Java API for streaming in the introduction. In terms of implementation, the Java library follows a scheme that is highly optimized and fairly unique among statically typed languages.

\(^2\) We follow the textbook distinction that “design” refers to how elements are separated into modules, while “architecture” refers to components-and-connectors, i.e., the machinery determining how elements of the design are composed. Our work shows a new library design, albeit one that would not be possible without a different underlying architecture.
In the Java 8 declarative stream processing API, operators fall into two categories: intermediate (always lazy – e.g., map and filter) and terminal (which can produce a value or perform side-effects – e.g., sum and reduce). For concreteness, let us consider the pipeline below. The expression (serving as a running example in this section) calculates the sum of squares of all values in an array of doubles.

```java
class StreamExample {
    public double sumOfSquaresSeq(double[] v) {
        double sum = DoubleStream.of(v)
            .map(d -> d * d)
            .sum();
        return sum;
    }
}
```

The code first creates a sequential, ordered `Stream` of `double` from an array that holds all values. The calls `map` and `sum` are an intermediate and a terminal operation respectively. The `map` operation returns a `Stream` and it is lazy. It simply declares the transformation that will occur when the stream will be traversed. This transformation is a stateless operation and is declared using a lambda function. The `sum` operation needs all the stream processed up to this point, in order to produce a value; this operation is eager and it is effectively the same as reducing the stream with the lambda `(x, y) -> x+y`.

Implementation-wise, the (stateless or stateful) operations on a stream are represented by objects chained together sequentially. A terminal operation triggers the evaluation of the chain. In our example, if no optimization were to take place, the `sum` operator would retrieve data from the stream produced by `map`, with the latter being supplied the necessary lambda expression. This traversing of the elements of a stream is realized through the `Spliterator` interface. This interface offers an API for traversing and partitioning elements of a source. A key method in this interface is `forEachRemaining` with signature

```java
void forEachRemaining(Consumer<? super T> action);
```

Normally, for the general case of standard stream processing, the implementation of `forEachRemaining` will internally call methods `hasNext` and `next` to traverse a collection, as well as `accept` to apply an operation to the current element. Thus, three virtual calls per element will occur.

However, stream pipelines, such as the one in our example, can be optimized. For the array-based `Spliterator`, the `forEachRemaining` method performs an indexed-based, do-while loop. The entire traversal is then transformed: instead of `sum` requesting the next element from `map`, the pipeline operates in the inverse order: `map` pushes elements through the `accept` method of its downstream `Consumer` object, which implements the `sum` functionality. (A `Consumer` in Java is an operation that accepts an argument and returns no result.) In this way, the implementation eliminates two virtual calls per step of iteration and effectively uses internal (push-style) iteration, instead of external (pull-style). This also enables further optimizations by the JIT compiler, often resulting in fully fused code.

The following (simplified for exposition) snippet of code is taken from the `Spliterators.java` source file of the Java 8 library and demonstrates this special handling, where a holds the source array and i indexes over its length:

```java
void forEachRemaining(Consumer<? super T> action); do { consumer.accept(a[i]); } while (++i < hi);
```

The push-style iteration can be seen in this code. Each of the operators applicable to a stream needs to support this inverted pattern by supplying an `accept` operation. That operation, in turn, will call `accept` on whichever `Consumer<T>` may be downstream. The consumer of a push stream will provide a consumer function that is instantiated into the
The dual of a push stream is a pull stream. Every combinator of a pull stream will build an iterator that will propagate some effect (e.g., apply a function \( f \) if this combinator is \( \text{map} \)) to each next element. C#, F# and Scala implement deferred execution over pipelines (all described in their respective sections) as pull streams. Java, on the other hand, supports push streams by default. Java additionally provides pull capabilities through the \textit{iterator} combinator – we shall see in Section 3 why this facility is not equivalent to full pull-style iteration functionality.

### 2.2 Scala

Scala is an object-functional programming language for the JVM. Scala has a rich object system offering traits and mixin composition. As a functional language, it has support for higher-order functions, pattern matching, algebraic data types, and more. Since version 2.8, Scala comes with a rich collections library offering a wide range of collection types, together with common functional combinators, such as \texttt{map}, \texttt{filter}, \texttt{flatMap}, etc. The most general streaming API for Scala is that for lazy transformations of collections, which also avoids the creation of intermediate, allocated results.

To achieve lazy processing, one has to use the \texttt{view} method on a collection. This method wraps a collection into a \texttt{SeqView}. The following example illustrates the use of \texttt{view} for performing such transformations lazily:

```scala
def sumOfSquareSeq (v : Array[Double]) : Double = {
  val sum : Double = v
    .view
    .map(d => d * d)
    .sum
  sum
}
```

Ultimately, \texttt{SeqView} extends \texttt{Iterable[A]}. \texttt{SeqView} acts as a factory for iterators. As an example, we can demonstrate the common \texttt{map} function by mapping the transformation function to the source’s \texttt{Iterable} iterator:

```scala
def map[T, U](source: Iterable[T], f: T => U) = new Iterable[U] {
  def iterator = source.iterator map f
}
```

The \texttt{Iterator}’s \texttt{map} function can then be implemented by delegation to the source iterator:

```scala
  def hasNext = source.hasNext
  def next() = f(source.next())
}
```

Note that there are 3 virtual calls (\texttt{next}, \texttt{hasNext}, \texttt{f}) per element pointed by the iterator. This is standard pull-style iteration, as in the unoptimized Java case, discussed earlier. Each operator has to “request” elements from the one supplying its input, rather than having a push-style pattern, with the producer calling the consumer directly.

---

3 Intuitively, in internal (push-style) iteration, there is no co-routining between the loop and the consumer. The latter is fully under the control-flow of the former. (The call consuming data returns – with none of its local data escaping – before the next data are produced.)
2.3 C#/%u2013/F#

C# is a modern object-oriented programming language targeting the .NET framework. An important milestone for the language was the introduction of several features in C# 3.0 in order to enable a more functional style of programming. These new features, under the umbrella of LINQ [12, 11], can be summarized as support for lambda expressions and function closures, extension methods, anonymous types and special syntax for query comprehensions. All of these enable the creation of new functional-style APIs for the manipulation of collections.

F# is a modern .NET functional-first programming language based on OCaml, with support for object-oriented programming, based on the .NET object system.

In C#, we can program data streams as fluent-style method calls:

```csharp
nums.Select(x => x * x).Sum();
```

or with the equivalent query comprehension syntactic sugar:

```csharp
(from x in nums
 select x * x).Sum();
```

In F#, stream manipulation can be expressed as a direct pipeline of various combinators.

```fsharp
nums |> Seq.map (fun x -> x * x) |> Seq.sum
```

C# and F# have near-identical operational behaviors and both C# methods (Select, Where, etc.) and F# combinators (Seq.map, Seq.filter, etc.) operate on IEnumerable<T> objects. The IEnumerable<T> interface can be thought of as a factory for creating iterators, i.e., objects with MoveNext and Current methods. The lazy nature of the iterators allows the composition of an arbitrary number of operators without worrying about intermediate materialization of collections between each call. For instance, the Select method returns an IEnumerable object that produces the iterator below:

```csharp
class SelectEnumerator<T, R> : IEnumerator<R> {
    private readonly IEnumerator<T> inner;
    private readonly Func<T, R> func;
    public SelectEnumerator(IEnumerator<T> inner,
        Func<T, R> func) {
        this.inner = inner;
        this.func = func;
    }
    bool MoveNext() { return inner.MoveNext(); }
    R Current { get { return func(inner.Current); } }
}
```

SelectEnumerator implements the IEnumerator<R> interface and delegates the MoveNext and Current calls to the inner iterator. From a performance point of view, it is not difficult to see that there is virtual call indirection between the chained enumerators. We have 3 virtual calls (MoveNext, Current, func) per element per iterator. Iteration is similar to Scala or to the general, unoptimized Java iteration: it is an external (pull-style) iteration, with each consumer asking the producer for the next element.

3 Stream Algebras

We next describe our stream library architecture and its design elements, including separate push and pull semantics, enhanced interpretations of a pipeline, optimizations and more.
3.1 Motivation

The goal of our work is to offer extensible streaming libraries. The main axis of extensibility that is not well-supported in past designs is that of pluggable semantics. In existing streaming libraries there is no way to change the evaluation behavior of a pipeline so that it performs, e.g., lazy evaluation, augmented behavior (e.g., logging), operator fusing, etc. Currently, the semantics of a stream pipeline evaluation is hard-coded in the definition of operators supplied by the library. The user has no way to intervene.

The original motivation for our work was to decouple the pull- vs. pull-style iteration semantics from the library operators. As discussed in Section 2, Java 8 streams are push-style by default, while Scala, C#, and F# streams are pull-style. A recent approach in the context of Haskell [22] performs a similar decoupling of push- vs. pull-style semantics through defunctionalization of the interface, yet affords no other extensibility.

Although Java 8 streams allow some pull-style iteration, they do not support fully pluggable pull-style semantics. The current pull-style functionality is via the \texttt{iterator()} combinator. This combinator is a terminal operator and adapts a push-style pipeline into an iterator that can be used via the \texttt{hasNext/next} methods. This is subtly different from changing the semantics of an entire pipeline into pull-style iteration.

For instance, the \texttt{flatMap} combinator takes as input a function that produces streams, applies it to each element of a stream, and concatenates the resulting streams. In a true pull-style iteration, it is not a problem if any of the intermediate streams happen to be infinite (or merely large): their elements are consumed as needed. This is not the case when a Java 8 \texttt{flatMap} pipeline is made pull-style with a terminal \texttt{iterator} call. Figure 1 shows a simple example. Stream \texttt{s} is infinite: it starts with zero and its step function keeps adding 2 to the previous element. The \texttt{flatMap} application produces modified copies of the infinite stream \texttt{s}, with each element multiplied by those of a finite array, \texttt{v}. Evaluation does not end until an out-of-memory exception is raised.\footnote{This is a known issue, which we have discussed with Java 8 streams implementors, and does not seem to have an easy solution. The underlying cause is that the type signatures of operators (e.g., \texttt{of} or \texttt{flatMap}) encode termination conditions as return values from downstream operators. For \texttt{flatMap} to avoid confusing the conditions from its parameter stream (result of \texttt{map} in this example) and its downstream (\texttt{iterator} in the example) it needs to evaluate one more element of the parameter stream than strictly needed, and that element happens to be infinite in the example.}

Our library design removes such issues, allowing pipelines with pluggable semantics. Although the separation of pull- and push-style semantics was our original motivation, it soon became evident that an extensible architecture offers a lot more options for semantic extensibility of a stream pipeline. We discuss next the new architecture and several semantic additions that it enables.
3.2 Stream as Multi-Sorted Algebras

Our extensible, pluggable-semantics design of the library is implemented using an architecture based on object algebras. Object algebras were introduced by Oliveira and Cook [13] as a solution to the expression problem [25]: the need to have fully extensible data abstraction while preserving the modularity of past code and maintaining type safety. The need for extensibility arises in two forms: adding new data variants and adding new operations. Intuitively, an object algebra is an interface that describes method signatures for creating syntax nodes (data variants). An implementation of the algebra offers semantics to such syntax nodes. Thus, new data variants (syntax nodes) are added by extending the algebra, while new operations (semantics) correspond to different implementations of the algebra.

We next present the elements of the object algebra approach directly in our streaming domain.

In our setting, the set of variants to extend are the different combinators: map, take (called limit in Java), filter, flatMap, etc. These are the different cases that a semantics of stream evaluation needs to handle. The “operations” on those variants declare the manipulation/ transformation that will be employed for all produced data items. We will use the term “behavior” for such operations.

Our abstraction for streams is a multi-sorted algebra. The two sorts that can be evolved as a family are the type of the stream, which can hold some type of values, and the type of the value produced by terminal operations. The signature of the former is called StreamAlg while the latter is ExecStreamAlg. The Exec* prefix is used to denote that this is the algebra for the types that perform execution. The algebras are expressed as generic interfaces and classes implementing these interfaces are factories. In our multi-sorted algebra these two distinct parts are connected with the subtyping relation and classes that implement the two interfaces can evolve independently, to form various combinations.

Intermediate Combinators. Our base interface, StreamAlg, is shown below.

```java
interface StreamAlg<C<T> {  
  <T> C<T> source(T[] array);  
  <T, R> C<R> map(Function<T, R> f, C<T> s);  
  <T, R> C<R> flatMap(Function<T, C<R>> f, C<T> s);  
  <T> C<T> filter(Predicate<T> f, C<T> s); 
}
```

As can be seen, StreamAlg is parameterized by a unary type constructor that we denote by the $\text{C}_<$ syntax. This is a device used for exposition. That is, for the purposes of our presentation we assume type-constructor polymorphism (a.k.a. higher-kinded polymorphism): the ability to be polymorphic on type constructors. This feature is not available in Java (although it is in, e.g., Scala).\(^5\) In our actual implementation, type-constructor polymorphism is emulated via a standard stylized construction, which we explain in Section 4.

Every combinator of streams is also a constructor of the corresponding algebra; it returns (creates) values of the abstract set. Each constructor of the algebra creates a new intermediate node of the stream pipeline and, in addition to the value of the previous node (parameter $s$) that it will operate upon, it takes a functional interface. (A functional interface has exactly one abstract method and is the type of a lambda in Java 8.)

---

\(^5\) The original object algebras work of Oliveira and Cook [13] did not require type-constructor polymorphism for its examples. Later work by Oliveira et al. [14] used type-constructor polymorphism in the context of Scala.
class PushFactory implements StreamAlg<Push> {
    public <T> Push<T> source(T[] array) {
        return k -> {
            for(int i=0 ; i < array.length ; i++){
                k.accept(array[i]);
            };
        };
    }
    public <T, R> Push<R> map(Function<T, R> mapper, Push<T> s) {
        return k -> s.invoke(i -> k.accept(mapper.apply(i)));
    }
}

Figure 2 Example of a PushFactory.

Terminal Combinators. The ExecStreamAlg interface describes terminal operators, which trigger execution/evaluation of the pipeline. These operators are also parametric. They can return a scalar value or a value of some container type (possibly parameterized by some other type). For instance, count can return Long, hence having blocking (synchronous) semantics, or it can return Future<Long>, to offer asynchronous execution.

Once again, this algebra is parameterized by unary type constructors and it also carries as a parameter the abstract stream type that it will pass to its super type, StreamAlg.

3.3 Adding New Behavior for Intermediate Combinators

We next discuss the extensibility that our design affords, with several examples of different interpretation semantics.

Push Factory. The first implementation in our library is that of a push-style interpretation of a streaming pipeline, yielding behavior equivalent to the default Java 8 stream library.

Push-style streams implement the StreamAlg<Push> interface (where Push is the container or carrier type of the algebra). All combinators return a value of some type Push<...>, i.e., a type expression derived from the concrete constructor Push. Our PushFactory implementation, restricted to combinators source and map, is shown below.

A Push<...> type is the embodiment of a push-style evaluation of a stream. It carries a function, which can be composed with others in a push-y manner. In the context of Java, we want to be able to assign lambdas to a Push<...> reference. Therefore we declare Push<X> as a functional interface, with a single method, void invoke(Consumer<T>). The Consumer<T> argument is itself a lambda (with method name accept) that takes as a parameter an item of type T and returns void. This consumer can be thought of as the continuation of the evaluation (hence the conventional name, k). The entire stream is evaluated as a loop, as shown in the implementation of the source combinator, above. source returns a lambda that takes as a parameter a Consumer<T>, iterates over the elements of a source, s, and passes elements one-by-one to the consumer.

Similarly, the map operator returns a push-stream embodiment of type Push<...>. This stream takes as argument another stream, s, such as the one produced by source, and
invokes it, passing it as argument a lambda that represents the map semantics: it calls its continuation, \( k \), with the argument (i.e., the element of the stream) as transformed by the mapping function. This pattern follows a similar continuation-passing-style convention as in the original Java 8 streams library. (As discussed in Section 2.1, this reversal of the pipeline flow enables significant VM optimizations and results in faster code.)

The next combinator, whichever it is, will consume the transformed elements of type \( R \). The implementation of other combinators, such as filter and flatMap, follows a similar structure.

**Pull Factory.** As discussed earlier, Java 8 streams do not have a full pull-style iteration capability. They have to fully realize intermediate streams, since the pull semantics is implemented as a terminal combinator and only affects the external behavior of an entire pipeline. (As we will see in our experiments of Section 6, this is also a source of inefficiency in practice.) Therefore, the first semantic addition in our library is pull-style streams.

Pull-style streams implement the \( \text{StreamAlg<Pull>} \) interface. In this case \( \text{Pull<T>} \) is an interface that represents iterators, by extending the \( \text{Iterator<T>} \) interface. For pull semantics, each combinator returns an anonymous class – one that implements this interface by providing definitions for the hasNext and next methods. In Figure 3 we demonstrate the implementation of the source and map operators, which are representative of others.

We follow the Java semantics of iterators (the effect happens in hasNext). Each element that is returned by the next method of the map implementation is the transformed one, after applying the needed mapper lambda to each element that is retrieved. The retrieval is realized by referring to the \( s \) object, which carries the iterator of the previous pipeline step.

Note how dissimilar the Push and Pull interfaces are (a lambda vs. an iterator with next and hasNext). Our algebra, \( \text{StreamAlg<C>} \) is fully agnostic regarding \( C \), i.e., whether it is Push or Pull.

**Log Factory.** With a pluggable semantics framework in place, we can offer several alternative interpretations of the same streaming pipeline. One such is a logging implementation. The log factory expresses a cross-cutting concern, one that interleaves logging capabilities with the actual execution of the pipeline. Although the functionality is simple, it is interesting in that it takes a mixin form: it can be merged with other semantics, such as push or pull factories. The code for the \( \text{LogFactory} \), restricted to the map and count operators, is shown in Figure 4.

The code employs a delegation-based structure, one that combines an implementation of an execution algebra (of any behavior for intermediates and orthogonally of any behavior for terminal combinators) with a logger. We parameterize \( \text{LogFactory} \) with an \( \text{ExecStreamAlg} \) and then via delegation we pass the intercepted lambda as the mapping lambda of the internal algebra. For example, if the developer has authored a pipeline \( \text{alg.reduce(0L, Long::sum, alg.map(x -> x + 2, alg.source(v)))} \), then, instead of using an \( \text{ExecPushFactory} \) that will perform push-style streaming, she can pass a \( \text{LogFactory<>}(\text{new ExecPushFactory()}) \) effectively mixing a push factory with a log factory.

**Fused Factory.** An interpretation can also apply optimizations over a pipeline. The optimization is applied automatically, as long as the user chooses an evaluation semantics that enables it. This is effected with an extension of a PullAlgebra that performs fusion of adjacent operations. Using a \( \text{FusedPullFactory} \) the user can transparently enable fusion
class PullFactory implements StreamAlg<Pull> {
    public <T> Pull<T> source(T[] array) {
        final int size = array.length;
        int cursor = 0;
        public boolean hasNext() { return cursor != size; }
        public T next() {
            if (cursor >= size)
                throw new NoSuchElementException();
            return array[cursor++];
        }
    }
    public <T, R> Pull<R> map(Function<T, R> mapper, Pull<T> s) {
        R next = null;
        public boolean hasNext() {
            while (s.hasNext()) {
                T current = s.next();
                next = mapper.apply(current);
                return true;
            }
            return false;
        }
        public R next() {
            if (next != null || this.hasNext()) {
                R temp = this.next;
                this.next = null;
                return temp;
            } else throw new NoSuchElementException();
        }
    }
}

Figure 3 Example of PullFactory functionality.

3.4 Adding New Combinators

Our library design also allows adding new combinators without changing the library code. In case we want to add a new combinator, we first have to decide in which algebra it belongs. For instance, we have added a take combinator without disturbing the original algebra definitions. A take combinator has signature \( \text{C}\langle T\rangle \text{ take}(\text{int} \; n) \) so it clearly belongs in \text{StreamAlg}. We have to implement the operator for both push and pull streams, but we want to allow the possibility of using take with any \text{ExecStreamAlg}. Our approach again uses delegation, much like the LogFactory, shown earlier in Figure 4. We create a generic \text{TakeStreamAlg}<\text{E}, \text{C}> interface and orthogonally we create an interface \text{ExecTakeStreamAlg}<\text{E}, \text{C}> that extends \text{TakeStreamAlg}<\text{C}> and \text{ExecStreamAlg}<\text{E}, \text{C}>. In the case of push streams, \text{ExecPushWithTakeFactory}<\text{C}> implements the interface we created, where \( \text{C} = \text{Push} \), by defining
class LogFactory<E_, C_> implements ExecStreamAlg<E, C> {
    ExecStreamAlg<E, C> alg;

    <T, R> C<R> map(Function<T, R> mapper, C<T> s) {
        return alg.map(i -> {
            System.out.print("map: " + i.toString());
            R result = mapper.apply(i);
            System.out.println(" \rightarrow " + result.toString());
            return result;
        }, s);
    }

    public <T> E<Long> count(C<T> s) {
        return alg.count(s);
    }
}

Figure 4 Example of LogFactory functionality.

the take operator. All other operators for the push case are inherited from the PushFactory supertype. The ExecPushWithTakeFactory<E> factory is parameterized by ExecStreamAlg<E, Push> alg. Generally, the factory can accept as parameter any algebra for terminal operators.

3.5 Adding New Behavior for Terminal Combinators

Future Factory. Our library design also enables adding new behavior for terminal combinators. The most interesting example in our current library components is that of FutureFactory: an interpretation of the pipeline that triggers an asynchronous computation. Instead of returning scalar values, a FutureFactory parameterizes ExecStreamAlg with a concrete type constructor, Future<X>.\(^6\) (This is in much the same way as, e.g., a PushFactory parameterizes StreamAlg with type constructor Push, in Figure 2.) Future is a type that provides methods to start and cancel a computation, query the state of the computation, and retrieve its result.

FutureFactory defines terminal operators count and reduce, to return Future<Long> and Future<T> respectively. Intermediate combinators are defined similarly to the terminal ones, but are omitted from the listing.

4 Emulating Type-Constructor Polymorphism

As noted earlier, our presentation so far was in terms of type-constructor polymorphism, although this is not available in Java. For our implementation, we simulate type-constructor polymorphism via a common technique. The same encoding has been used in the implementation of object-oriented libraries – e.g., in type classes for Java [6] and in finally tagless interpreters for C# [10]. The technique was also recently presented formally by Yallop and White [27], and used to represent higher-kinded polymorphism in OCaml.

In this encoding, for an unknown type constructor C<>, the application C<T> is represented as Appc<, T>, where T is a Java class and t is a marker class that identifies the type constructor C. For example, our stream algebra shown in Section 3.2 is written in plain Java as follows:

\(^6\) That is, Future is our own class, which extends the Java library class FutureTask, and not to be confused with the Java library java.util.concurrent.Future interface.
class ExecFutureFactory<C<_>> implements ExecStreamAlg<Future, C> {
    private final ExecStreamAlg<Id, C> execAlg;
    public <T> Future<Long> count(C<T> s) {
        Future<Long> future = new Future<>(() -> {
            return execAlg.count(s).value;
        });
        future.run();
        return future;
    }
    public <T> Future<T> reduce(T identity,
                                BinaryOperator<T> accumulator,
                                C<T> s) {
        Future<T> future = new Future<>(() -> {
            return execAlg.reduce(identity, accumulator, s).value;
        });
        future.run();
        return future;
    }
}

Figure 5 Count and reduce operators in FutureFactory.

public interface App<C, T> { }
public interface StreamAlg<C> {
    <T> App<C, T> source(T[] array);
    <T, B> App<C, B> map(Function<T, B> f, App<C, T> app);
    <T, R> App<C, R> flatMap(Function<T, App<C, R>> f, App<C, T> app);
    <T> App<C, T> filter(Predicate<T> f, App<C, T> app);
}

A subtle point arises in this encoding: given C, how is t generated? This class is called the “brand”, as it tags the application so that it cannot be confused with applications of other type constructors; this brand should be extensible for new types that may be added later to the codebase. This means that (a) t should be a fresh class name, created when C is declared; and (b) there should be a protocol to ensure that the representation is used safely.

Brand freshness. The freshness of the brand name is addressed by declaring t as a nested class inside the class of the new type constructor. Since t exists at a unique point in the class hierarchy, no other class may declare a brand that clashes with it, and its declaration happens at the same time as C is declared. In the following, we see the encoding of the type constructor Pull<T>, with its t brand:

public interface Pull<T> extends App<Pull.t, T>, Iterator<T> {
    static class t { }
    static <A> Pull<A> prj(App<Pull.t, A> app) { return (Pull<A>) app; }
}

We see that the encoding above has an extra method prj, which does a downcast of its argument. The OCaml encoding of Yallop and White needs two methods inj and prj (for “inject” and “project”) that cast between the concrete type and the instantiation of the type application. In Java, we define prj, which takes the representation of the type application and returns the actual Push<T> instantiation. In contrast to OCaml, Java has subtyping, so inj functions are not needed: a Pull<T> object can always be used as being of type App<Pull.t, T>. The Iterator interface in the declaration above is not related to the encoding, but is part of the semantics of pull-style streams.
Long result = Id.prj(alg.count(
    alg.filter(x -> x % 2L == 0,
    alg.source(v)))).value;

Figure 6 Count of filtered items.

<E, C> App<E, Long> cart(ExecStreamAlg<E, C> alg) {
    return alg.reduce(0L, Long::sum,
        alg.flatMap(
            x -> alg.map(y -> x * y,
                alg.source(v2)),
            alg.source(v1)));
}

Figure 7 Sum of the cartesian product.

Safely using the encodings. This encoding technique has a single unchecked cast, in the
prj function. The idea is that the cast will be safe if the only way to get a value of type
App<Pull.t, X> (for any X) is if it is really a value of the subtype, Pull<X>. This property
clearly holds if values of type App<Pull.t, X> (or values of any type involving Pull.t) are
never constructed. In the Yallop and White technique for OCaml, this is ensured syntactically
by the “freshness” of the brand, t, which is private to the type constructor. In Java, the
property is ensured by convention: every subtype S of App has a locally defined brand t and
no subtype of App<S.t, X> other than S exists.

Type expressions without type-constructor polymorphism. Another detail of the encoding
is the representation of type expressions that are not parametric according to a type
constructor; for those we need an identity type application, Id.

Using the class above, the type expression List<Integer> can then be represented as
Id<List<Integer>>.

5 Using Streams

With the encoding of type-constructor polymorphism, our description of the library features
is complete. A user can employ all combinators to build pipelines, and can flexibly choose
the semantics of these pipelines.

The example of Figure 6 declares a pipeline that filters long integers and then counts them.
The expression assumes an implementation, alg, of a stream algebra. Note that the prefix,
Id.prj, and suffix, value, of the pipeline expression are only needed for our type-constructor
polymorphism simulation.

Similarly, Figure 7 constructs a sum of the cartesian product pipeline between two arrays.
The factory object (implementing the algebras) is factored out and becomes a parameter of the
method cart.
The above can be used with any of the various semantics factories presented in Section 3, depending on the kind of evaluation the user wants to perform. In Figure 8 we present a summary of all the combinations of factories that can be used. The first five expressions return a scalar value `Long` and the last two a `Future<Long>`.

### 6 Performance

It is interesting to assess the performance of our approach, compared to the highly optimized Java 8 streams. Since our techniques add an extra layer of abstraction, one may suspect they introduce inefficiency. However, there are excellent reasons why our design can yield high performance:

- Object algebras are used merely for pipeline construction and not for execution. Once the data processing loop starts, it should be as efficient as in standard Java streams.
- Our design offers fully pluggable semantics. This is advantageous for performance. We can leverage fusion of combinators, proper pull-style iteration without materialization of full intermediate results, and more.

Our benchmarks aim to showcase these two aspects. In this sense, some of the benchmarks are unfair to Java 8 streams: they explicitly target cases for which we can optimize better. We point out when this is the case.

We use a set of microbenchmarks offering various combinations of streaming pipelines:

- **reduce**: a sum operation.
- **rfilter/reduce**: a filter-sum pipeline.
- **rfilter/map/reduce**: a filter-map-sum pipeline.
- **rcart/reduce**: a nested pipeline with a `flatMap` and an inner operation, with a `map` (capturing a variable), to encode the sum of a Cartesian product.
- **rfused filters**: 8 consecutive filter operations and a count terminal operation. The implementation is push-style for Java 8, push-style, pull-style & fused for our library.
- **fused maps**: 8 consecutive map operations and a count terminal operation. The implementation is push-style for Java 8, push-style, pull-style & fused for our library.
- **rcount**: a count operation (pull-style).
- **rfilter/count**: a filter-count pipeline (pull-style).

---

The benchmark programs are adapted from our earlier benchmarking study [2] of streams in various languages. As shown in that study, Java 8 streams typically significantly outperform other implementations. Still, performance of streaming libraries lags behind hand-optimized code. This is to be expected, since hand-written code can remove most overhead of lazy evaluation, by fusing the consumer of data with the producer. JDK developers have shown significant interest in future VM optimizations that will allow Java streams to approach the performance of hand-written code [16].
Streams à la carte: Extensible Pipelines with Object Algebras

- rfilter/map/count: a filter-map-count pipeline (pull-style).
- rcart/take/count: a nested pipeline with aflatMap and an inner operation, with a map, to encode taking the first few elements of a Cartesian product and then counting them (pull-style).

Although our library is not yet full-featured, it faithfully (relative to Java 8 streams) implements the facilities tested in these benchmarks.

Input: All tests were run with the same input set. For all benchmarks except cart/reduce and cart/take/count we used an array of \( N = 10,000,000 \) Long integers (boxed),\(^8\) produced by \( N \) integers with a range function that fills the arrays procedurally. The cart/reduce test iterates over two arrays. An outer one of 10,000,000 long integers and an inner one of 10. For the cart/take/count test, the sizes of the inner and outer arrays are reversed and the take operator draws only the first \( n = 100,000 \) elements. Fusion operations use 1,000,000 long integers.

Setup: We use a Fedora Linux x86_64 operating system (version 3.17.4-200.fc20) that runs natively on an Intel Core i5-3360M vPro 2.8GHz CPU (2 physical x 2 logical cores). The total memory of the system is 4GB. We use version 1.8.0.25-4.b18 of the Open JDK.

Automation: We used the Java Microbenchmark Harness (JMH) [17]: a benchmarking tool for JVM-based languages that is part of the OpenJDK. JMH is an annotation-based tool and takes care of all intrinsic details of the execution process, in order to remove common experimental biases. The JVM performs JIT compilation so the benchmark author must measure execution time after a certain warm-up period to wait for transient responses to settle down. JMH offers an easy API to achieve that. In our benchmarks we employed 10 warm-up iterations and 10 proper iterations. We also force garbage collection before benchmark execution. Additionally, we used 2 VM-forks for all tests, to measure potential run-to-run variance. We have fixed the heap size to 3GB for the JVM to avoid heap resizing effects during execution.

Results: The benchmarks are cleanly grouped in 4 sets:

- In Figure 9a we present the results of the first 4 benchmarks: reduce, filter/reduce, filter/map/reduce, and cart/reduce. These are “fair” comparisons, of completely equivalent functionality in the two libraries. As can be seen, the performance of our push algebra implementation matches or exceeds that of Java 8, validating the claim that our approach does not incur undue overheads.

- Figure 9b presents the results for the next two benchmarks: fused filters and fused maps. These benchmarks are intended to demonstrate the improvement from our fusing semantics. The Java 8 implementation compared is push-style. Still, our fused pull-style semantics yield a successful optimization, outperforming even the efficient, push-style iteration. Due to our design, this optimization is achieved modularly and independently of the rest of the stream implementation.

- Figure 9c includes the next 3 benchmarks: count, filter/count, and filter/map/count. These are benchmarks of semantically uneven implementations. Java 8 streams support

\(^8\) Specialized pipelines for primitive types is not supported in our library, but should be a valuable future engineering addition.
Figure 9 Microbenchmarks on JVM in milliseconds / iteration (average of 10).
pull-style functionality by transforming the stream into an iterator, but this is not equivalent to full pull-style iteration. As can be seen, a true pull semantics for all operators can be much faster.

Finally in Fig 9d we show the cart/take/count benchmark. This contains a pipeline that is pathological for the Java pull-style streams, in much the same way as the infinite evaluation of Section 3.1. (Push-style streams have the same pathology, by definition: they cannot exploit the fact that only a small number of results are needed in the final operator.) Instead of an infinite stream we reproduce the nested flatMap/map pipeline but with the larger array being the nested one. As flatMap needs to materialize nested arrays (effectively applying the inner map function to create the inner stream) it suffers from the effect of inner allocations. Our proper pull-style pipeline does not present this behavior. The result is spectacular in favor of our pull algebra implementation, because of the small number of elements actually needed by the take operator.

7 Discussion

We next present observations related to our library design and its constituent elements.

7.1 Fluent API

Object Algebras drive the “interpretation” of streams in our work, so a nested, reversed pattern occurs when declaring the combinators of a pipeline: instead of “of(...).filter(...).count()”, our pipeline looks like “alg.count(alg.filter(..., alg.source(...)))”. This reversed pattern follows the declaration order of the combinators, contradicting the natural ordering of a fluent API.

We created an experimental fluent API in Java using static methods in the interface of the object algebra, but the result was cumbersome. In contrast, we created skeletal C# and Scala implementations of a fluent API for our library design, for demonstration purposes. (Our object algebra streaming architecture applies to any modern OO language with generics, so C# and Scala libraries based on the same principles can be developed in the future.)

In C# the user can create a fluent API through the use of extension methods. Extension methods enable the user to “add” methods to existing types without creating a new derived type, recompiling, or modifying the original type. Extension methods are simply a compiler shorthand that enables static methods to be called with instance syntax. Using that feature, the user can create a static class enclosing extension methods that capture the reversed flow.

Figure 10 shows the relevant C# code snippet. Extension methods are defined for the function type, Func<F, App<C, T>>. The user wraps all methods of an algebra with methods that, instead of returning C<T>, return a function that takes as parameter an algebra object. The algebra object is, thus, hidden from the original code and introduced implicitly in calls to such returned functions.

The above technique enables fluent ordering, as shown in the Example method of the listing. The fluent API also has immediate side benefits in current programming tools: the user is able to retrieve the list of combinators via the intelligent code completion feature of the IDE.

We also retrieve fluency in Scala using a similar technique, enabled by the feature of implicit classes [21] as shown in Figure 11.

9 Static methods in interfaces is a feature introduced in Java 8.
static class Stream {
    public static Func<F, App<C, T>> OfArray<F, C, T>(T[] array)
        where F : IStreamAlg<C>
    { return alg => alg.OfArray(array); }

    public static Func<F, App<C, T>> Filter<F, C, T>(this Func<F, App<C, T>> streamF,
        Func<T, bool> predicate)
        where F : IStreamAlg<C>
    { return alg => alg.Filter(streamF(alg), predicate); }

    public static Func<F, App<E, int>> Count<F, E, C, T>(this Func<F, App<C, T>> streamF)
        where F : IExecStreamAlg<E, C>
    { return alg => alg.Count(streamF(alg)); }

    public static App<E, int> Example<E, C, F>(int[] data, F alg)
    {
        Func<F, App<E, int>> streamF =
            Stream(OfArray(data)
                .Filter(x => x % 2 == 0)
                .Count());
        return streamF(alg);
    }
}

Figure 10 Example of Fluent API creation in C#.

7.2 Generalized Algebraic Data Types

We observe that the encoding of type-constructor parameterization that we employed in Section 4 is sufficient for emulating Generalized Algebraic Data Types (GADTs) in Java. GADTs are algebraic data types that permit data constructors to specify their exact return type. The standard example of a GADT is a generic expression evaluator, which can be captured via an abstract visitor that uses type-constructor polymorphism:

abstract class Visitor<R_>() {
    abstract R<Integer> caseIntLit (IntLit expr);
    abstract R<Boolean> caseBoolLit (BoolLit expr);
    abstract R<Integer> casePlus (Plus expr);
    abstract <Y> R <Y> caseIf (If<Y> expr);
}

The emulation of GADTs with type-constructor polymorphism is not new – it is, for instance, mentioned by Altherr and Cremet [1] and by Oliveira and Cook [13].

As discussed in Section 4 the safety of the emulation depends on following the convention that the only subtype of App<S.t, ...> is S.

8 Related Work

“Stream programming” is an overloaded term, encompassing streaming algorithms (a subarea of the theory of algorithms), synchronous dataflow, reactive systems, signal processing applications, spreadsheets, and embedded systems [4, 19, 24]. These are conceptually related to our work in terms of intuitions, but hardly related in terms of the techniques employed. A more appropriate context for our work is streams in the sense of the Java Stream API [15], which provides stream-like functionality for data collections. In the rest of this section, we discuss related work both from dedicated streaming systems, and from streaming APIs built on top of general-purpose programming languages.
object Stream {
  trait StreamAlg[C[_]] {
    def ofArray[T](array: Array[T]) : C[T]
    def filter[T](f : T => Boolean, app : C[T]) : C[T]
  }
  trait ExecStreamAlg[C[_], E[_]] extends StreamAlg[C] {
    def count[T](app : C[T]) : E[Long]
  }
    alg => alg.ofArray(array)
  }
  trait Push[T]
  trait Pull[T]
  type Id[A] = A
  implicit class RichReader[T, C[_], E[_], F <% ExecStreamAlg[C, E]](func : F => C[T]) {
    def filter(p : T => Boolean) : F => C[T] = {
      alg => alg.filter(p, func(alg))
    }
    def count() : F => E[Long] = {
      alg => alg.count(func(alg))
    }
  }
  def example[T, C[_], E[_]](array: Array[Int]) : F => C[T] = {
    Stream.ofArray[Int, C, E, ExecStreamAlg[C, E]](array)
      .filter((x:Int) => x%2==0)
      .count()(alg)
  }
}

Figure 11 Example of Fluent API creation in Scala.

Streaming DSLs and interpreters. From the implementor’s point of view, our stream algebras expose a DSL for stream programming. The DSL is embedded in Java and takes advantage of the optimizing nature of the underlying JIT-based implementation. In a similar fashion, the StreamIt language, which needed a special implementation with stream-specific analyses and optimizations [23], was recently implemented atop the Java platform, as StreamJIT [3]. However, while StreamJIT required a full implementation effort, our technique is more lightweight, being available as a Java library, with an API extending that of native Java streams. StreamIt generally has a very different focus from our work: although it offers flexible, declarative combinators, its domain of applicability is multimedia streams of very large data, as opposed to general functional programming over data collections.

The DirectFlow DSL of Lin and Black also supported push and pull configurations for information-flow systems with extensible operators [9]. Compared to our design, it uses a compiler, exposes the internal “pipes” that connect different stream operators, and requires the management (instantiation and connection) of objects for these pieces of the flow graph.

The operator fusion semantics that we showed is only one example of stream-based optimizations. Other optimizations that can be unlocked by our technique are operator reordering, redundancy elimination in the pipeline, and batching [8].

Our DSL representation follows a shallow embedding with Church-style encodings [13]; as Gibbons and Wu have demonstrated, this makes it natural and simple to implement the interpreter in recursive style [5].

Our design permits not only the definition of completely new operators, but also composite
operators that reuse existing ones. This expressiveness enables modularity in our design in a manner similar to the modularity offered by the composite operators of high-level streaming languages such as SPL [7].

**Collections and big data (including Java streams).** Su et al. showed how Java streams can support different compute engines in the same pipeline [20], for the domain of distributed data sets. Unlike our design, there is no infrastructure for the change of evaluation engine without affecting the library code.

Our approach can process the pipeline, so in that respect is similar to the “application DSL” of ScalaPipe [26]. ScalaPipe operates as a program generator. It generates an AutoPipe application that produces C, OpenCL etc. The high level program is written in Scala. The target program is C.

StreamFlex offers high-throughput, low-latency streaming capabilities in Java, taking advantage of ownership types [18]. StreamFlex is an extension of Java (due to type system additions), and, furthermore, comes with an altered JVM to support real time execution. It focuses on event processing and especially on the scheduling of filters (so that priority is given to the threads that handle the stream without GC pressuring, etc.).

Compared to the above, our work is smoothly integrated in the language (as an embedded, internal DSL – effectively a plain library). We discover the DSL hidden inside the Java Streams API and show how its implementation can improve, with pluggable and modular semantics, via object algebras.

Svensson and Svenningsson demonstrated how pull-style and push-style array semantics can be combined in a single API using a defunctionalized representation and a shallow embedding for their DSL [22]. However, they propose a new API and a separate DSL layer that passes through a compiler, while we remain compatible with existing Java-like stream APIs. Furthermore, our approach enables full semantic extensibility, beyond just changing the pull vs. pull style of iteration.

**9 Future Work and Conclusions**

We presented an alternative design for streaming libraries, based on an object algebras architecture. Our design requires only standard features of generics and is, thus, widely applicable to modern OO languages, such as Java, Scala, and C#. We implemented a Java streaming library based on these principles and showed its significant benefits, in terms of transparent semantic extensibility, without sacrificing performance.

Given our extensible library design, there are several avenues for further work. The clearest path is towards enriching the current library implementation with shared-memory parallel evaluation semantics, cloud evaluation semantics, distributed pipeline parallelism, GPU processing, and more. Since we expose the streaming pipeline, such additions should be transparent to current evaluation semantics, and can even be performed by third-party programmers.

**Acknowledgments.** We thank the anonymous reviewers and artifact evaluation reviewers for their constructive comments. We are grateful to Paul Sandoz (Oracle) for help with Java 8 streams and valuable suggestions. Our work was funded by the Greek Secretariat for Research and Technology under the “MorphPL” Excellence (Aristeia) award.
